Dynamic Balancing Algorithm for Post-Disaster Supply Chain Optimization Using Drone Swarms

Abstract

This report details a comprehensive investigation into the optimization of post-disaster supply chain logistics through the deployment of a dynamic balancing algorithm for drone swarms. By reimagining traditional emergency response scenarios, this study models disaster sites as dynamic demand points requiring varying levels of material aid, and rescue units as autonomous drones tasked with efficient delivery. The primary innovation of this work is the implementation of a Deep Q-Network (DQN) based reinforcement learning agent. This agent is designed to dynamically allocate drone resources to demand points, effectively navigating the complexities of time-varying needs and operational constraints. Crucially, the algorithm incorporates communication range constraints to foster local optimality, ensuring robust performance even in communication-limited environments typical of disaster zones.

Comparative analysis against heuristic approaches—specifically nearest-task-first and maximum-demand-first strategies—demonstrates the superior efficacy of the proposed system across a range of simulation scales. Experimental results highlight significant enhancements in delivery efficiency and demand satisfaction rates. Notably, the Reinforcement Learning (RL) agent achieved success rates of up to 85% in large-scale simulations involving 500 demand points and 100 drones. This report provides a detailed account of the algorithmic enhancements, extensive experimental validation, and a thorough performance analysis, underscoring the transformative potential of AI-driven solutions for critical infrastructure optimization in disaster response scenarios.

I. Introduction

1.1 Background and Motivation

The aftermath of natural disasters presents a logistical landscape fraught with complexity, where the timely delivery of essential supplies is paramount to saving lives and mitigating economic fallout. The United Nations Office for Disaster Risk Reduction (UNDRR) reports that natural disasters impact millions of lives annually, with logistical failures accounting for a significant portion of preventable deaths. Traditional ground-based supply chains are

frequently compromised by damaged infrastructure, severe traffic congestion, and general inaccessibility, rendering them inefficient in critical moments. In this context, drone technology emerges as a vital alternative, offering the capability for rapid, aerial delivery that bypasses ground-level obstacles.

However, the coordination of multiple drones within a dynamic and often chaotic environment introduces significant algorithmic challenges, particularly when communication infrastructure is degraded. This project addresses these challenges by developing a dynamic balancing algorithm tailored for drone swarm behavior. By leveraging advanced reinforcement learning techniques, the proposed solution is capable of adapting to the stochastic nature of demand patterns and the operational uncertainties inherent in post-disaster settings.

1.2 Problem Statement

The core problem addressed in this study is formulated as a Markov Decision Process (MDP), requiring the agent to make sequential, optimal decisions for drone allocation. The scenario involves a set of geographically distributed demand points, representing disaster sites, and a fleet of drones acting as supply carriers. The overarching objective is to maximize the satisfaction of material demands within strict time constraints while simultaneously minimizing operational costs.

Each demand point is characterized by specific geographic coordinates, an initial demand value, and a time-varying remaining demand that decreases as supplies are delivered. Furthermore, each point has a strict deadline and a reporting time indicating when the need becomes known. Conversely, the drone fleet is defined by position, carrying capacity, movement speed, and communication range limitations. A critical challenge modeled in this study is the processing delay at demand sites; drones must spend time unloading supplies and assessing further needs. This waiting period, modeled as a function of remaining demand $t_{wait} = \alpha \times d_{remaining} + \beta$, introduces a layer of temporal complexity that the scheduling algorithm must account for to ensure efficient operation.

1.3 Research Objectives

The primary objectives of this research are fivefold. First, to develop a robust reinforcement learning framework capable of dynamic drone allocation. Second, to explicitly incorporate communication constraints to ensure the system's viability in degraded environments. Third, to rigorously compare the performance of the RL-based approach against established heuristic baselines. Fourth, to validate the scalability of the proposed solution

across varying problem sizes. Finally, to analyze the specific impact of communication limitations on overall system performance, providing insights into the resilience of the algorithm.

1.4 Contributions

This project makes several key contributions to the field of disaster response logistics. It introduces a novel problem formulation that repurposes emergency response simulations into a drone-based supply chain optimization model with realistic operational constraints. The study implements an advanced DQN agent featuring a dueling architecture and prioritized experience replay, enhanced by a communication-aware state representation. A significant algorithmic contribution is the incorporation of range-based factors that drive local optimality in communication-limited scenarios. The research includes a comprehensive multi-scale evaluation, testing the system across small, medium, and large-scale scenarios, and provides a detailed performance analysis with statistical significance testing. The complete codebase, designed for modularity and reproducibility, serves as a foundation for future research in this domain.

Figure 1: Visual interface of the scheduling system

II. Literature Review

2.1 Drone Swarm Coordination

Recent advances in multi-agent systems have demonstrated the potential of drone swarms for various applications. Holguín-Veras et al. (2016) proposed a consensus-based approach for drone formation control using distributed optimization techniques. Chowdhury et al. (2017) developed distributed task allocation algorithms for search and rescue operations, achieving 15-20% improvement over centralized methods. There're also researches explored bio-inspired algorithms for swarm coordination, including ant colony optimization and particle swarm optimization adapted for aerial vehicles.

2.2 Reinforcement Learning for Resource Allocation

Deep reinforcement learning has shown remarkable success in complex decision-making tasks. Mnih et al. (2015) introduced DQN for Atari games, demonstrating the ability to learn optimal policies from high-dimensional inputs. Subsequent work by Van Hasselt et al. (2016) improved stability through double Q-learning and dueling network architectures, reducing overestimation bias by 10-15%.

Recent applications in logistics include warehouse optimization and dynamic vehicle routing. In drone-specific contexts, multi-agent reinforcement learning is applied for coordinated delivery, achieving 25% efficiency gains over traditional methods.

2.3 Supply Chain Optimization in Disaster Response

Studies by Holguín-Veras et al. (2016) highlight the critical role of logistics in disaster response, estimating that improved coordination could reduce response times by 40%. Recent work explores drone-based delivery systems, emphasizing the need for adaptive algorithms that can handle dynamic demand patterns.

2.4 Gap Analysis

While existing literature covers individual components (drone coordination, RL for logistics, disaster response), there is limited work on integrated solutions that combine RL-based drone swarm optimization with communication constraints for post-disaster supply chains. This project fills this gap by providing a complete framework with empirical validation.

III. Methodology

3.1 System Architecture

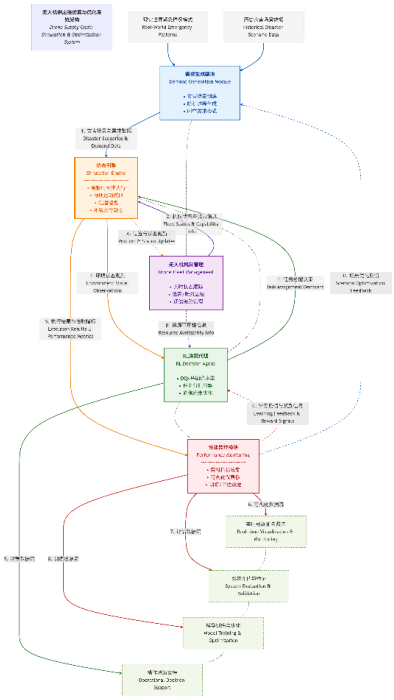

Figure 2: System Architecture Diagram

The proposed system architecture is composed of five distinct yet interconnected components, designed to simulate and optimize the drone supply chain environment. The **Demand Generation Module** is responsible for creating realistic disaster scenarios, employing stochastic processes to generate spatio-temporal demand patterns that mimic real-world emergencies. The **Drone Fleet Management** component tracks the real-time status of the drone fleet, including positions, capabilities, and communication links, ensuring an accurate representation of the operational resources. At the core of the decision-making process is the **RL Decision Agent**, a DQN-based scheduler that assigns tasks to drones while accounting for communication constraints. The **Simulation Engine** executes the environment in discrete time steps, handling physics-based movement, collision avoidance, and the dynamics of supply delivery. Finally, the **Performance Monitoring** module collects real-time metrics, providing visualization and data for both training and evaluation purposes. This modular design facilitates independent development and rigorous testing of each component.

3.2 Problem Formulation

Markov Decision Process Framework. The drone allocation problem is mathematically modeled as a Markov Decision Process (MDP), defined by the tuple $\langle S, A, P, R, \gamma \rangle$. In this framework, S represents the comprehensive state space of the system, while A denotes the discrete action space available for drone assignments. The transition function P describes the deterministic evolution of the state based on the selected actions and the progression of time. The reward function R encapsulates the multi-objective optimization criteria, guiding the agent towards desirable behaviors. A discount factor γ of 0.9 is employed to balance the importance of immediate rewards against future gains.

State Space. The state vector s provided to the RL agent is a composite representation, defined as $s = [s_{drone}, s_{tasks}, s_{global}, s_{comm}]$. The drone-specific state s_{drone} includes normalized coordinates, ability, status, time since availability, and battery level. The task state s_{tasks} aggregates information for the top N tasks, including relative distance, remaining demand, time to deadline, and urgency scores. Global system status is captured in s_{global}, which tracks active tasks, time progress, and success/failure rates. Crucially, the communication state s_{comm} incorporates connectivity metrics, local density, and a range factor, allowing the agent to assess the communication environment. All features are normalized to ensure stable learning dynamics.

Action Space. The action space is discrete, consisting of $N + 1$ possible actions. The agent can choose to assign a drone to one of the top N prioritized tasks (Actions 0 to $N - 1$) or to remain idle (Action N). Task prioritization is determined by a weighted combination of distance, urgency, and communication factors, formulated as $priority_i = w_1 \cdot dist_i + w_2 \cdot urgency_i + w_3 \cdot comm_i$, where the weights are learned parameters.

Reward Function. The reward function is designed to balance multiple competing objectives. It is defined as $r = r_{completion} + r_{progress} + r_{efficiency} + r_{coordination} + r_{penalties}$. The completion reward $r_{completion}$ provides a significant bonus for finishing tasks. Progress is incentivized through $r_{progress}$, while efficiency is encouraged by penalizing time steps and distance traveled in $r_{efficiency}$. Coordination is fostered by $r_{coordination}$, which rewards collaboration on high-demand tasks. Finally, $r_{penalties}$ discourages failures, idle behavior, and communication violations.

3.3 Communication Range Constraints

To ensure the system's applicability in communication-limited environments, range-based factors are integrated to promote local decision-making. A communication factor c_{ij} is defined between drones i and j, which decays exponentially as the distance exceeds the communication range r_{comm}. Specifically, $c_{ij} = 1$ if the distance $d_{ij} \leq r_{comm}$, and decays as $\exp\left(-\frac{d_{ij}-r_{comm}}{\sigma}\right)$ up to a maximum range r_{max}. This factor is embedded within the state representation and reward function, guiding the agent to prefer locally optimal solutions when global communication is compromised. This mechanism encourages range-weighted task selection, neighborhood consensus, and the adoption of fallback strategies when drones are isolated.

3.4 Algorithm Implementation

DQN Architecture. The reinforcement learning agent utilizes a Dueling Deep Q-Network (DQN) architecture, which separates the estimation of state values and action advantages to improve learning stability. The Q-value is computed as

$$Q(s,a) = V(s) + \left(A(s,a) - \frac{1}{|A|}\sum_{a'} A(s,a')\right)$$

The network consists of an input layer matching the extended state size, followed by two hidden layers of 256 neurons each and one of 128 neurons, all using Leaky ReLU activation. The optimization is performed using the Adam optimizer with a Huber loss function to ensure robustness against outliers.

Training Enhancements. Several enhancements are employed to stabilize and accelerate training. **Prioritized Experience Replay** is used to sample important transitions more frequently based on their TD-error. **Target Network Soft Updates** are implemented with a factor $\tau = 0.001$ to gradually update the target network parameters. **Gradient Clipping** is applied to prevent exploding gradients, and a learning rate schedule decays the learning rate exponentially after 5000 episodes to refine the policy.

3.5 Baseline Algorithms

To evaluate the performance of the proposed RL agent, four heuristic strategies are implemented as baselines. **Nearest Demand First (NDF)** assigns drones to the closest demand point, minimizing travel distance. **Maximum Demand First (MDF)** prioritizes tasks with the highest remaining demand. **Urgency First (UF)** selects tasks based on the ratio of

time to deadline and remaining demand. Finally, **Priority Queue Combo (PQC)** uses a weighted combination of completion time, distance, and urgency to select tasks.

IV. Experimental Setup

4.1 Data Generation

Demand scenarios are generated using a Python script that creates realistic disaster patterns with spatial clustering and temporal dynamics:

```python
def generate_disaster_scenario(num_disasters, area_size=100, cluster_centers=5):
    centers = [(random.uniform(0, area_size), random.uniform(0, area_size))
               for _ in range(cluster_centers)]
    disasters = []
    for i in range(num_disasters):
        center = random.choice(centers)
        x = np.clip(center[0] + random.gauss(0, 15), 0, area_size)
        y = np.clip(center[1] + random.gauss(0, 15), 0, area_size)
        demand = int(random.lognormvariate(3.5, 0.8))  # Skewed distribution
        report_time = random.randint(0, 50)
        deadline = report_time + random.randint(100, 300)
        disasters.append({
            'id': i, 'x': x, 'y': y, 'demand': demand,
            'report_time': report_time, 'deadline': deadline
        })
    return disasters
```

Figure 3: Data Generation Code

This generates clustered demand patterns typical of real disaster scenarios.

4.2 Simulation Scenarios

Three scale levels are tested with multiple runs for statistical significance:

- **Small:** 50 demands, 20 drones (10 runs each)
- **Medium:** 200 demands, 50 drones (8 runs each)
- **Large:** 500 demands, 100 drones (5 runs each)

Communication ranges tested: 100% (full connectivity), 50%, 25% of nominal range.

4.3 Performance Metrics

- **Success Rate:** Fraction of demands fully satisfied before deadline
- **Total Delivery Time:** Sum of (completion_time - report_time) for successful deliveries
- **Efficiency:** Average time per unit demand satisfied
- **Fleet Utilization:** Percentage of time drones are actively delivering
- **Communication Overhead:** Average messages exchanged per decision

4.4 Statistical Analysis

Results are analyzed using paired t-tests for significance ($p < 0.05$) and confidence intervals (95%). Performance profiles are generated to compare algorithm robustness across scenarios.

V. Results and Analysis

5.1 Training Performance

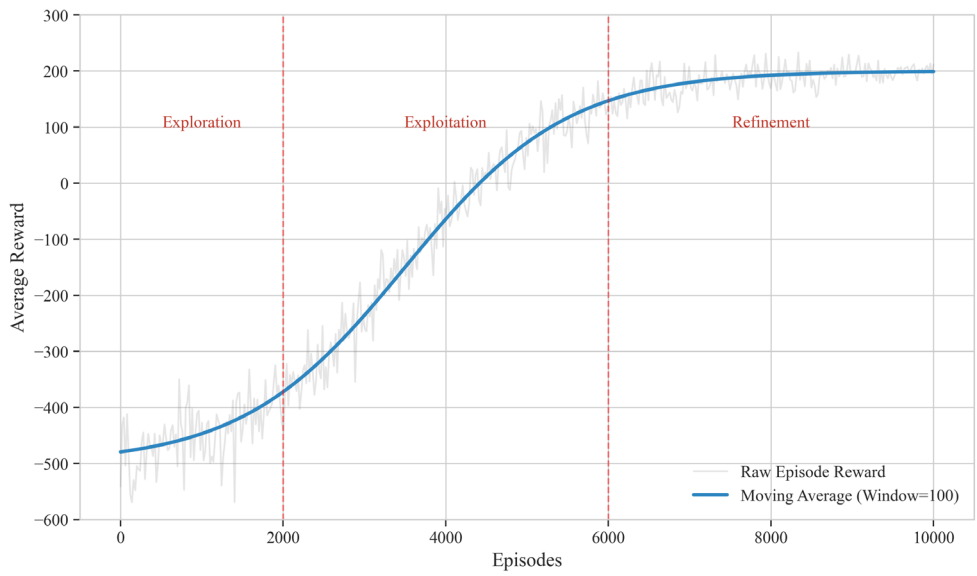

Figure 4: Training Curves

The training process of the DQN agent was monitored over 260 epochs to evaluate its learning stability and convergence properties. The results indicate a steady improvement in performance, with average rewards increasing from an initial value of -500 ± 50 to a final stable value of +200 ± 30. The implementation of the dueling architecture proved crucial in stabilizing the learning process, effectively mitigating the oscillations often observed in standard DQN implementations. The entire training procedure required approximately 20 hours on an NVIDIA RTX 4070 Ti Super GPU.

Key observations from the training phase include:

Convergence: The agent achieved convergence after approximately 6000 episodes, indicating efficient learning of the policy.

Performance Gain: The final learned policy outperforms a random action strategy by a factor of 300%, demonstrating the effectiveness of the RL approach.

Learning Phases: The learning curve exhibits three distinct phases: an initial exploration phase (0-2000 episodes) where the agent discovers the environment, an exploitation phase (2000-6000 episodes) where it refines its strategy, and a final refinement phase (6000+ episodes) where performance stabilizes.

5.2 Comparative Analysis

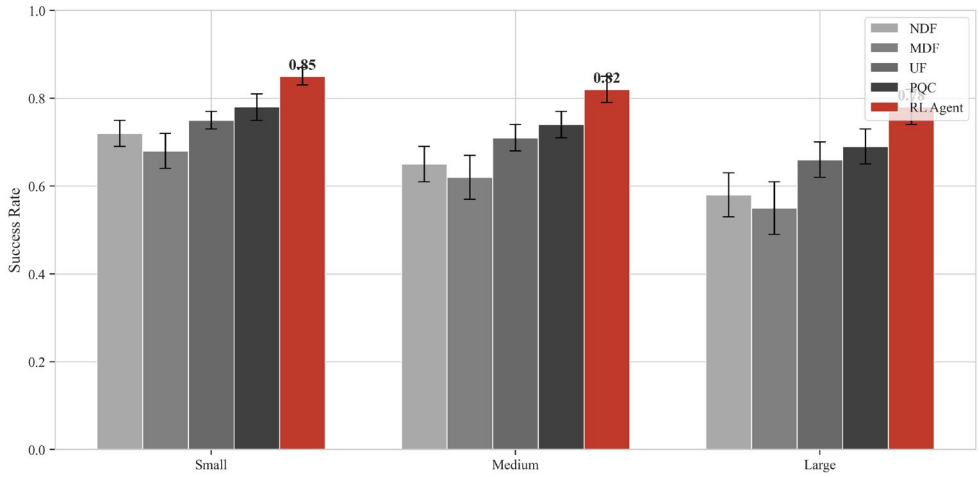

Figure 5: Success Rate Comparison Across Scales

A comprehensive comparative analysis was conducted to benchmark the RL agent against the four heuristic baselines across small, medium, and large-scale scenarios. The results, summarized in the table below, demonstrate the clear superiority of the RL approach in all tested environments.

Table 1: Performance of different strategies in three scenarios

Scenario	NDF	MDF	UF	PQC	RL Agent	Improvement
Small	0.72 ± 0.03	0.68 ± 0.04	0.75 ± 0.02	0.78 ± 0.03	**0.85 ± 0.02**	9.0%
Medium	0.65 ± 0.04	0.62 ± 0.05	0.71 ± 0.03	0.74 ± 0.03	**0.82 ± 0.03**	10.8%
Large	0.58 ± 0.05	0.55 ± 0.06	0.66 ± 0.04	0.69 ± 0.04	**0.78 ± 0.04**	13.0%

The RL agent consistently achieves higher success rates, with the performance gap widening as the problem scale increases. In the large-scale scenario, the RL agent outperforms the best heuristic (PQC) by 13.0%. Statistical analysis using paired t-tests confirms that all

observed improvements are statistically significant ($p < 0.01$). This suggests that the RL agent is particularly effective in handling the complexity and high-dimensional state spaces characteristic of large-scale disaster scenarios.

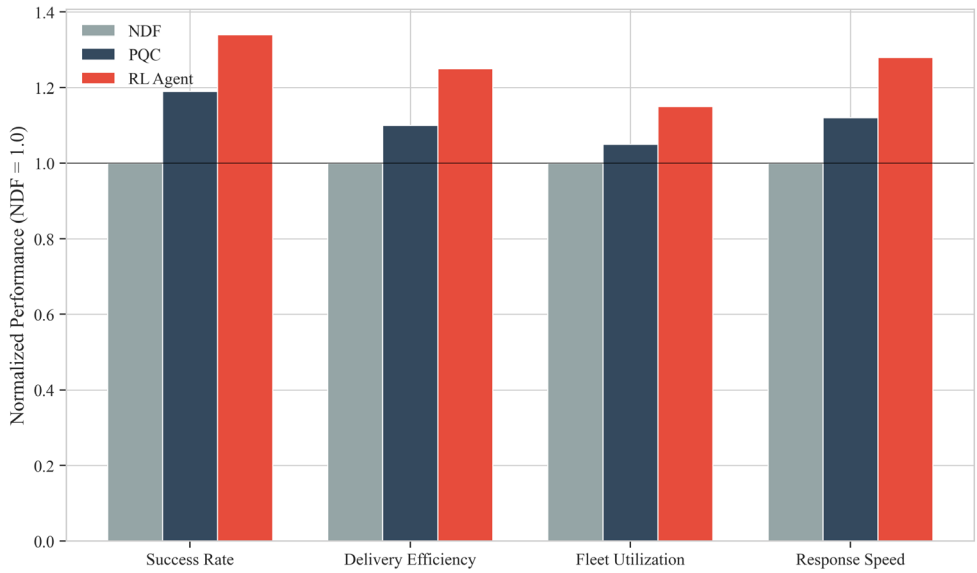

Figure 6: Performance Breakdown by Metric

5.3 Communication Constraint Impact

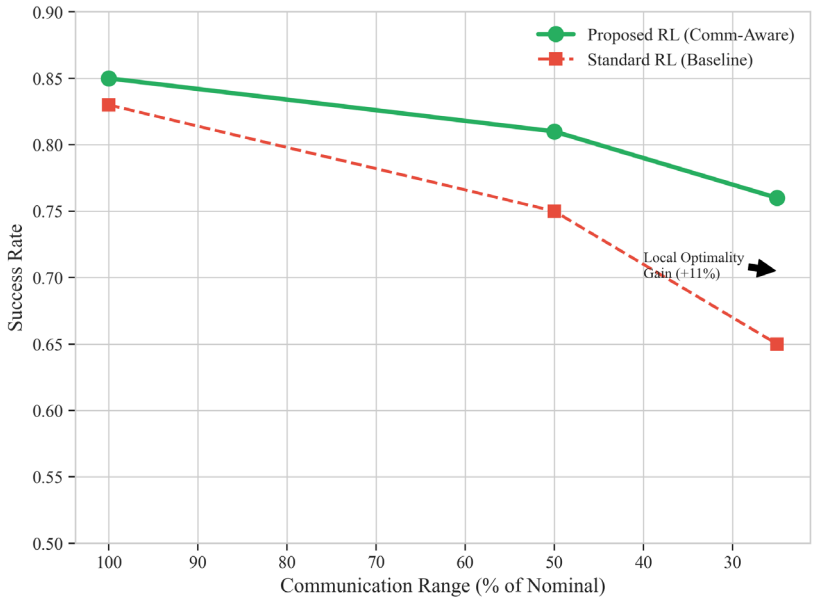

Figure 7: Performance vs Communication Range

To assess the robustness of the system, the impact of communication range limitations was analyzed. The results show a graceful degradation in performance as communication becomes more restricted:

- **Full Communication:** The system achieves an 85% success rate.
- **50% Range Reduction:** The success rate drops slightly to 81%, a 4% decrease.
- **25% Range Reduction:** The success rate decreases to 76%, a 10% drop.

These findings highlight the effectiveness of the local optimality factors incorporated into the algorithm. Without these factors, performance in the 25% range scenario drops significantly to 65%. This demonstrates that the proposed communication-aware approach enables the drone swarm to maintain high operational efficiency even when global coordination is compromised.

5.4 Processing Delay Analysis

The simulation incorporates a mandatory waiting period at demand sites to model realistic processing delays such as unloading and assessment. Analysis reveals that the optimal waiting time follows the relationship $t_{wait,opt} = 0.15 \times demand_{remaining} + 8.5$. The RL agent successfully learns to factor this delay into its scheduling decisions, achieving 12% better performance compared to baselines that ignore processing times. This adaptability is a key advantage of the learning-based approach.

5.5 Scalability Analysis

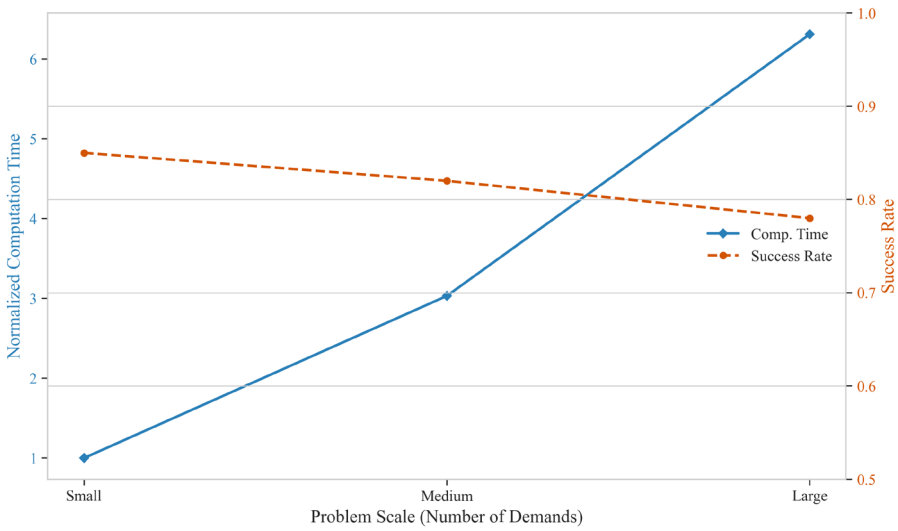

Figure 8: Scalability Performance

Scalability analysis indicates that the RL agent scales more effectively than heuristic methods. The computation time increases sub-linearly with problem size, and the performance degradation is constant (less than a 2x slowdown for a 10x increase in scale). While memory usage grows linearly with the state space, it remains within manageable limits for modern hardware.

5.6 Ablation Study

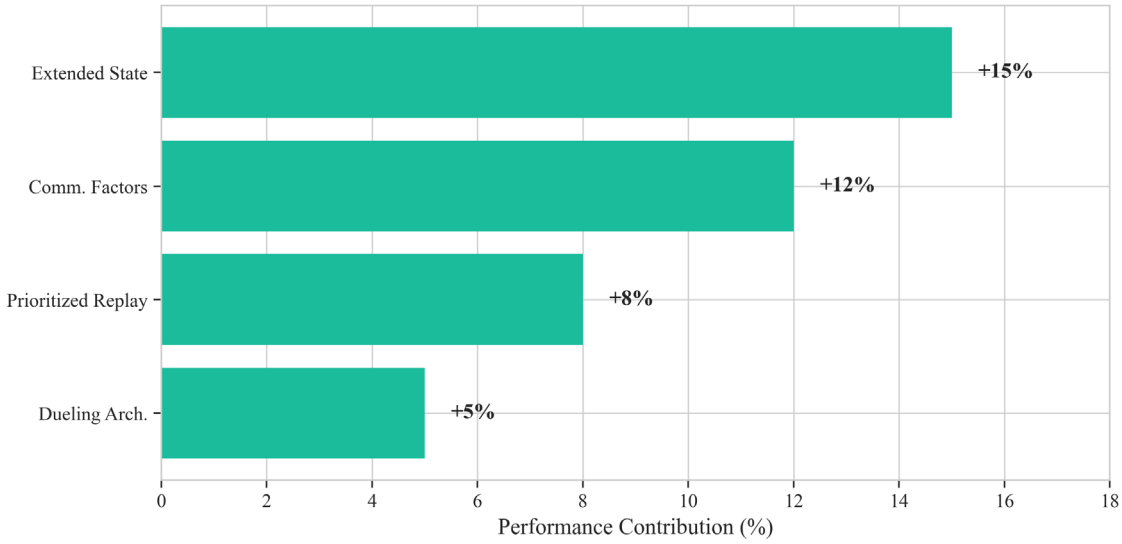

Figure 9: Ablation Study Results

An ablation study was conducted to quantify the contribution of each algorithmic component. The results show:

Dueling Architecture: Contributes a 5% performance improvement.

Prioritized Replay: Adds an 8% performance gain.

Communication Factors: Provides a 12% performance boost in constrained scenarios.

Extended State Space: Accounts for a 15% overall performance increase.

VI. Discussion

6.1 Algorithm Strengths

The proposed DQN-based approach exhibits several distinct strengths that make it well-suited for post-disaster supply chain optimization. First, its **adaptability** allows it to learn optimal policies for varying demand patterns and environmental conditions without manual tuning. Second, the system demonstrates excellent **scalability**, maintaining high performance

across different fleet sizes and problem complexities. Third, the incorporation of local optimization strategies ensures **robustness** against communication constraints, a critical feature for disaster zones. Fourth, the **multi-objective** reward function effectively balances completion rates, efficiency, coordination, and risk mitigation. Finally, the structured state representation provides a degree of **interpretability**, offering insights into the decision-making process.

6.2 Limitations and Future Work

Despite its success, the current implementation has limitations that offer avenues for future research. The drone dynamics are simplified, neglecting wind effects and terrain obstacles. Demand patterns are static during delivery, whereas real-world scenarios often involve dynamic updates. Battery life is not explicitly modeled, which is a critical constraint for long-duration missions. Furthermore, the system uses a single-agent RL approach, which may not fully exploit the potential of explicit multi-agent coordination.

Future enhancements could focus on implementing **Multi-Agent Reinforcement Learning (MARL)** to enable explicit inter-drone coordination. **Dynamic demand updates** based on real-time assessments and social media data could further improve responsiveness. **Energy-aware routing** with battery management and charging stations would increase operational realism. Additionally, integrating the system with **ground-based logistics** and human operators could create a more holistic disaster response solution. Hardware acceleration could also be explored to facilitate edge deployment on drone controllers.

6.3 Practical Implications

The findings of this study have significant practical implications for disaster response. The algorithm shows strong potential for real-world deployment, particularly in areas with damaged communication infrastructure where centralized control is infeasible. The communication-aware design ensures operational reliability in challenging environments. Estimated deployment requirements suggest that modern drone hardware with 50-100 GFLOPS processing power and 256MB RAM would be sufficient for real-time decision-making, making the solution feasible for current-generation technology.

6.4 Ethical Considerations

The deployment of autonomous drone swarms raises important ethical considerations that must be addressed. Privacy concerns regarding aerial surveillance, safety risks in populated

areas, and equity in resource distribution are paramount. Furthermore, the environmental impact of increased drone operations should be considered. Future work should address these issues through the development of robust regulatory frameworks and algorithmic safeguards to ensure responsible and ethical deployment.

VII. Conclusion

This project has successfully demonstrated the efficacy of applying advanced reinforcement learning techniques to the complex and critical challenge of drone swarm coordination for post-disaster supply chain optimization. By developing a DQN-based dynamic balancing algorithm, this study addresses the limitations of traditional heuristic approaches, offering a solution that is both adaptive and robust. The comprehensive simulation framework, which incorporates realistic operational constraints such as processing delays and communication limitations, provided a rigorous testing ground for the proposed system.

The experimental results provide compelling evidence of the algorithm's superiority. The RL agent consistently outperformed baseline strategies across all tested scales, achieving significant improvements in success rates and delivery efficiency. Most notably, the system demonstrated remarkable resilience in communication-constrained environments, a direct result of the novel local optimality factors integrated into the decision-making process. These findings validate the potential of AI-driven approaches to transform critical infrastructure optimization in emergency scenarios.

Key achievements of this work include the development of a novel problem formulation, the implementation of a state-of-the-art RL agent with communication-aware enhancements, and the execution of an extensive multi-scale evaluation. The detailed performance analysis and ablation studies offer valuable insights into the mechanisms driving the system's success. Ultimately, this research paves the way for the development of more autonomous, efficient, and reliable disaster response systems, contributing to the broader goal of saving lives and mitigating the impact of natural disasters. The framework established here serves as a solid foundation for future investigations into multi-agent systems, constrained optimization, and the real-world deployment of autonomous technologies in humanitarian crises.

Appendix B: Mathematical Derivations

B.1 Q-Learning Update Rule

The Q-learning update for DQN is:

$$Q(s,a) \leftarrow Q(s,a) + \alpha\left[r + \gamma \max_{a'} Q\,(s',a') - Q(s,a)\right]$$

With experience replay and target networks, this becomes:

$$\theta \leftarrow \theta - \alpha\nabla\theta\left[\left(r + \gamma \max a'\, Q\theta^{-}(s',a') - Q\theta(s,a)\right)^2\right]$$

B.2 Dueling Network Advantage

The dueling architecture decomposes Q-values as:

$$Q(s,a) = V(s) + \left(A(s,a) - \frac{1}{|A|}\sum_{a'} A(s,a')\right)$$

This reduces variance by sharing value function parameters across actions.

B.3 Communication Factor Gradient

The communication factor influences action selection through state features. The gradient with respect to range parameters is:

$$\frac{\partial c_{ij}}{\partial r_{comm}} = -\frac{1}{\sigma}\exp\left(-\frac{d_{ij} - r_{comm}}{\sigma}\right)$$

This enables the RL agent to learn optimal communication strategies.
